Abstract

A detailed study of critical spreading in the one-dimensional pair contact process is performed using a recently devised reweighting method. The results confirm the validity of a generalized hyperscaling relation among the (nonuniversal) spreading exponents, and support the assertion that the critical point location does not depend on the particle density ϕ . It appears that the exponents z and $\delta + \eta$, once thought to be invariant, exhibit a systematic dependence on ϕ .

I. INTRODUCTION

The model studied in this work is a not-to-distant cousin of directed percolation. In view of his extensive and continuing contributions to percolation theory, it gives me great pleasure to dedicate this work to my friend George Stell, who has taught me much about physics (and perhaps more about music).

When viewed as a spatio-temporal process (the oriented axis representing time), directed percolation exhibits an absorbing-state phase transition, that is, a transition between an active state and one in which the dynamics is frozen. Critical phenomena at absorbing-state phase transitions are of longstanding interest in statistical physics [1,2], being found, for example, in models of epidemics [3], catalytic kinetics [4,5], surface growth [6], and self-organized criticality [7–10]. The best studied models of this kind, the contact process (CP) and directed percolation (DP), are relevant to experiments on interface pinning [11] and sand flow [12]. The transition between active and absorbing states arises out of a conflict between two opposing processes (e.g., creation and annihilation); when continuous (as is often the case), it falls generically in the DP universality class [13–15]. When two or more absorbing states exist and are connected by a symmetry operation, as in branching and annihilating random walks, the asymptotic dynamics is dominated by a domain-growth process, and a new kind of critical behavior appears [16–19].

Unusual critical behavior also appears in models that can become trapped in one of an infinite number of absorbing configurations (INAC). (More precisely, the number of absorbing configurations grows exponentially with the system size. There is no special symmetry linking the different absorbing configurations.) Models of this sort were introduced to describe surface catalysis [20–22]; their critical properties have been studied in detail by various workers [23–30]. In one dimension, the pair contact process (PCP) [24], and other models with INAC exhibit static critical behavior in the DP class [25,31], but the critical exponents δ , η , and z , associated with the spread of activity from a localized seed are *nonuniversal*, varying continuously with the particle density ϕ in the environment [25,26,30,32]. [These exponents

are defined via the asymptotic ($t \rightarrow \infty$) power laws: survival probability $P(t) \sim t^{-\delta}$, mean activity $n(t) \sim t^\eta$, and mean-square distance from the seed $R^2(t) \sim t^z$.] This anomalous aspect of critical spreading for INAC can be traced to a long memory in the dynamics of the order parameter, ρ , arising from a coupling to an auxiliary field (the local particle density, ϕ), that remains frozen in regions where $\rho = 0$ [27,29,30]. Theoretical understanding of models with INAC remains incomplete. Muñoz et al. were able to construct a plausible field theory (a set of stochastic partial differential equations), for models with INAC, and to show that the static critical behavior is that of DP [27]. Formally eliminating the auxiliary field, they obtained a closed equation for the order parameter, in which a memory term appears; simulations of this theory reproduce the nonuniversal exponents observed in simulations of particle models [32]. On the other hand, the phenomenon of nonuniversal spreading exponents has so far resisted analysis via renormalization group or other theoretical methods.

Studies of spreading in models with INAC have yielded several clues toward understanding nonuniversality [25,26]. First, the *location* of the critical point (the critical parameter value, p_c in the PCP), does not depend on ϕ , even as the exponents vary. Second, the exponent z , and the sum $\delta + \eta$, are roughly independent of ϕ . Third, the exponents δ , η , and z obey a generalized form of the hyperscaling relation derived by Grassberger and de la Torre for models with a unique absorbing configuration [26,33]:

$$\eta + \delta + \frac{\beta}{\nu_{||}} = \frac{dz}{2} . \quad (1)$$

For models with a unique absorbing configuration, the scaling relation $\delta = \beta/\nu_{||}$ holds, and one recovers the original hyperscaling relation [34]. When the static critical behavior falls in the DP universality class, $\beta/\nu_{||} = \delta_{DP}$ independent of ϕ ; in what follows we shall write Eq. (1) in the form $\eta + \delta + \delta_{DP} = dz/2$. Recently, Ódor et al. reported a weak dependence of p_c on the particle density in the environment [35]. In this work I describe extensive simulations of the PCP, using a recently-devised reweighting method [36], and improved data analysis. The results shed light on all three of the above-mentioned clues.

The balance of this paper is devoted to defining the model and simulation algorithm

(Sec. II), some observations on the implications of a critical point shift for scaling (Sec. III), outlining the simulation method (Sec. IV), and presenting the simulation results (Sec. V). We close (in Sec. VI) with a discussion of our findings and their relation to previous work on nonuniversal spreading in models with an infinite number of absorbing configurations.

II. MODEL AND SCALING PROPERTIES

Jensen’s pair contact process (PCP) [24], is an *interacting particle system*: a Markov process whose state space is a set of particle configurations on a lattice [37,38]. Here we consider the one-dimensional version: each site of $\mathcal{Z}^d$ is either vacant or occupied. Each nearest-neighbor (NN) pair of occupied sites (“particles”) has a rate p of mutual annihilation, and a rate $1 - p$ of attempted creation. In a creation event involving particles at sites i and $i+1$, a new particle may appear (with equal likelihood) either at site $i-1$ or at $i+2$, provided the chosen site is vacant. (Attempts to place a new particle at an occupied site fail.) In an annihilation event the sites occupied by a NN pair are simply vacated. The PCP exhibits an active phase for $p < p_c$; above this value the system falls into an absorbing configuration devoid of NN pairs, but that typically contains a substantial density, ϕ , of isolated particles. The most precise available estimate for the critical parameter is $p_c = 0.077090(5)$ [31]. (Here and in what follows, numbers in parentheses denote an uncertainty estimate in the last figure or figures.) Note that the active regime corresponds to $p < p_c$.

Previous studies leave little doubt that the static critical behavior of the PCP belongs to the universality class of directed percolation. Jensen and Dickman found that the critical exponents β , γ , θ (which govern, respectively, the stationary mean of, variance of, and initial decay of the order parameter), and $\nu_{\parallel}$ and $\nu_{\perp}$ (which govern the divergence of the correlation time and correlation length as one approaches the critical point), are all consistent with DP values [25]. More recently, the order parameter moment ratios and cumulants were found to be the same as those of other models belonging to the DP universality class [31]. The process of *critical spreading*, i.e., the propagation of initially localized activity in a system at

the critical point, is more subtle. Critical spreading in the PCP is studied by simulating the process at the critical point, with an initial condition generated by placing a single NN pair of particles (the “seed”) into a configuration otherwise devoid of pairs. In this work, as in previous studies, the sites outside the seed bear a uniform particle density ϕ . (The particles may be placed in a random or a regular fashion.) The critical point for spreading, $p_c(\phi)$, is defined operationally as the value for which the survival probability, mean number of pairs, and mean-square distance from the seed follow power laws. All earlier studies, except that of Ódor et al., have found $p_c(\phi) = p_c$, independent of ϕ .

The surprising result of the critical spreading studies is that only for a particular value of ϕ , the so-called *natural density* ϕ_{nat} , do the spreading exponents δ , η and z assume DP values [25]. The natural density is defined as the mean particle density in absorbing configurations generated by the process itself, at p_c , starting from a homogeneous (e.g., fully occupied) configuration. One may, equivalently, define ϕ_{nat} as the particle density in the critical stationary state, in the thermodynamic limit. An environment with $\phi > \phi_{nat}$ should favor spreading (and one with $\phi < \phi_{nat}$ should hinder it), since the higher the particle density in the environment, the more pairs will be formed per creation event.

A kind of spreading phenomenon also arises in the stationary state due to spontaneous fluctuations. In the critical stationary state, we can expect to find inactive regions of all sizes; the particle density in large inactive regions is ϕ_{nat} . When activity spreads into such regions, it should follow the same scaling behavior as critical spreading with ϕ_{nat} . Since the exponents governing survival and growth of activity in the stationary state are subject to the scaling relations $\delta = \beta/\nu_{||}$ and $z = 2\nu_{\perp}/\nu_{||}$, with β , $\nu_{\perp}$ and $\nu_{||}$ taking DP values in the stationary state, it follows that the spreading exponents take their usual DP values as well, for $\phi = \phi_{nat}$. In an environment with $\phi \neq \phi_{nat}$, the advance of the active region is no longer equivalent to the spread of activity in the stationary state, and the spreading exponents are not constrained to take DP values. Of course, the interior of the active region must eventually relax to the critical stationary state, with a particle density ϕ_{nat} , regardless of the exterior particle density ϕ .

In simulations one finds that for $\phi < \phi_{nat}$ the exponent δ is larger than the DP value, so that the survival probability decays more rapidly. η and z are smaller than the corresponding DP values, showing that diminishing the particle density hampers spreading, as expected. For $\phi > \phi_{nat}$ these trends are reversed. The variations in δ and η are quite dramatic: the former changes by more than a factor of four, and the latter by about two, as ϕ is varied between the extreme values of 0 and 1/2. The changes in z and $\delta + \eta$ are much smaller, amounting to about 5% over the full range of ϕ ; it was suggested that the observed variations, which were not much larger than numerical uncertainties, could be attributed to corrections to scaling, suggesting the appealing simplification that z and $\delta + \eta$ are in fact independent of ϕ [26]. Since z and $\delta + \eta$ have only to do with surviving trials (the latter governs the growth in the number of pairs in such trials: $n_s \sim t^{\delta+\eta}$), lack of dependence of these quantities on ϕ would imply that the latter only affects the survival probability, and not the asymptotic scaling of surviving trials.

Two observations should be made before discussing further details. First, the above pattern of scaling properties (DP static behavior, nonuniversal exponents taking DP values only at the natural density, no apparent shift in p_c , and near-constancy of z and $\delta + \eta$), has been confirmed in other one-dimensional models with INAC (the so-called dimer reaction [25], the threshold transfer process [26], and an evolution model with real-valued site variables [39]), in models with a long memory of the initial configuration [29,30], and in a field theory intended to describe models with INAC [27,32]. Second, spreading in two-dimensional models with INAC appears to be more complex [29], and may not exhibit power-law scaling for all initial conditions [30], although the static critical behavior again falls in the DP class [28,40].

III. CRITICAL POINT SHIFTS AND SCALING

How will shift in the critical point affect the spreading process? Before attempting an answer, it is helpful to define the critical point with somewhat greater precision. In the PCP

the *bulk* critical point p_c is defined such that in the infinite-size limit, the stationary order parameter (density of NN pairs) is zero for $p \geq p_c$ (subcritical regime) and scales as $\rho \sim \Delta^\beta$ for $\Delta \equiv p_c - p \gtrsim 0$. Now consider a spreading process, in which activity is initially localized (for example, at a single NN pair in the PCP). The subcritical regime for spreading is defined as the set of p values for which the survival probability $P(t) \rightarrow 0$ as $t \rightarrow \infty$; the critical value for spreading is then

$$p_c(\phi) \equiv \min\{p : \lim_{t \rightarrow \infty} P(t) = 0\} . \quad (2)$$

In simulations, $p_c(\phi)$ is identified as the value for which the survival probability, mean population $n(t)$, and mean-square spread $R^2(t)$ all follow asymptotic power laws, which define the exponents δ , η and z . (In the PCP, $n(t)$ and R^2 refer to NN pairs; in the simpler CP, of course, they represent the number and spread of particles. Note that in the supercritical regime, $n \sim t^d$ and $R^2 \sim t^2$, that is, the finite fraction of trials that survive spread with a finite velocity, and have a finite bulk density. For $\Delta \gtrsim 0$, we expect a crossover from the exponents η and z at short times to the supercritical growth laws at longer times.) We are not aware of any proof that P , n , and z follow power laws at $p_c(\phi)$. But it is known that in the CP, away from the critical point, the approach to the stationary state, be it active or absorbing, is exponential [37,41]; in some simpler cases, such as compact directed percolation, a power-law can be demonstrated explicitly [42,43]. (On the other hand, the CP with quenched disorder appears to have a *logarithmic* time-dependence at the critical point, and power-law away from the critical point [44,45]). In any event, we shall assume that in the PCP, $p_c(\phi)$ can be identified via the power-law criterion.

Consider the mean population $n_s(t)$, in trials that survive until (at least) time t . By definition, $n_s(t) \geq 1$, for *any* value of p , but for $p > p_c(\phi)$, $n_s(t)$ remains bounded as $t \rightarrow \infty$, while for $p < p_c(\phi)$ it grows without bound. Unbounded growth also obtains at $p_c(\phi)$ if we assume that $P(t)$ decays slower than exponentially at the critical point (absenting a proof, we merely observe that exponential decay would be incompatible with scale-invariance!).

That is because the rate of extinction is proportional to the probability of having exactly

one pair:

$$-\frac{dP}{dt} = pP(t) \Pr [n_s(t) = 1] . \quad (3)$$

If $n_s(t)$ remains bounded, then $\Pr [n_s(t) = 1] > 0$, and Eq. 3 implies exponential decay of the survival probability. Assuming the power laws noted above for P and n , we have $n_s(t) \sim t^{\eta+\delta}$; unbounded growth of $n_s(t)$ at $p_c(\phi)$ implies $\eta + \delta \geq 0$.

The above observations are helpful in analyzing the implications of a critical point shift. Suppose that $p_c(\phi) < p_c$ for spreading in an environment with $\phi < \phi_{nat}$. (That is, to compensate for the “hostile” environment, the spreading critical point shifts to a value that lies in the bulk *supercritical* regime.) This means that for $p_c(\phi) < p < p_c$, the bulk is supercritical, but the spreading process always dies. At the critical point $p_c(\phi)$, the spreading trials that do survive for long times have a nonzero bulk density $\rho_b \sim [p_c - p_c(\phi)]^\beta$, since the interior of the active region must eventually attain the stationary state. At long times, this interior region, having a finite density, makes the dominant contribution to n_s and R^2 , implying that $n_s \sim (R^2)^{d/2} \sim t^{zd/2}$, which in turn implies the hyperscaling relation

$$\eta + \delta = \frac{dz}{2} , \quad (4)$$

rather than Eq. (1). [Eq. (4) describes spreading at first-order transitions between different absorbing states, for example in compact DP or the voter model [46]. In this case Eq. (4) follows directly from Eq. (1), since $\beta = 0$.]

Suppose, conversely, that $p_c(\phi) > p_c$ for $\phi > \phi_{nat}$, i.e., the “friendly” environment permits a spreading trial to survive indefinitely even if the bulk is subcritical. If so, then for $p_c < p \leq p_c(\phi)$, a surviving trial must have its activity concentrated in an annular region (or at two fronts, in one dimension), since the order parameter vanishes in the bulk. (One may think of the activity as a “chemical wave” that converts one kind of absorbing configuration, with $\phi > \phi_{nat}$, into another, with $\phi \simeq \phi_{nat}$.) In one dimension, moreover, the width of this active zone must grow fast enough that $n_s(t)$ grows without bound as $t \rightarrow \infty$.

Summarizing, if the critical point for spreading depends on the surrounding particle density, then we should expect, for $\phi < \phi_{nat}$, that the activity profile $\rho_a(x, t)$ in surviving

trials is plateaulike, and that the spreading exponents satisfy Eq. (4); for $\phi > \phi_{nat}$, we would expect the activity profile to be bimodal, with an inactive central region. There are no arguments, to our knowledge, prohibiting such behaviors. (Indeed, such modifications of usual spreading were reported for two-dimensional models in Refs. [28] and [29].) But if the activity profiles do not take the anticipated forms, it is likely that either no shift in $p_c(\phi)$ exists, or that the asymptotic long-time behavior has not been probed.

IV. SIMULATION METHOD

Initial configuration. For each trial, we construct an initial configuration with a single NN pair or “seed” at the center of the system (sites $L/2$ and $L/2+1$ on a line of L sites). We consider three values of ϕ : zero, $1/2$, and the natural density 0.242 . For $\phi = 1/2$ the sites immediately to either side of the seed are vacant, beginning an alternating sequence that frames seed. For the studies at ϕ_{nat} we generate random initial configurations as follows. Consider the sites $i \geq L/2 + 1$. Since $L/2 + 1$ is occupied, it must be followed by a gap of $g \geq 1$ vacant sites before the next occupied site. We generate a sequence of gaps $g_i = 1 + m_i$ where the m_i are a set of independent Poisson random variables with mean $\langle m_i \rangle = \phi_{nat}^{-1} - 2$, in order to reproduce the natural particle density. (The same procedure is applied to sites $L, L-1, \dots, 1$. In each trial we keep a record of the extent of the active region. To prepare for the following trial we only need to reset sites within that region; since it is usually much smaller than the full system, this results in a considerable speedup.)

Dynamics. We maintain a list of the N_p current nearest-neighbor pairs. At each step we choose a pair at random from the list, and a process (annihilation with probability p , creation with probability $1 - p$). In case of annihilation, the pair is simply removed. For creation, we choose a site i at random from the two sites neighboring of the pair, and place a new particle at i if it is currently vacant. (If i is occupied the configuration remains the same.) The time increment associated with a step is $\Delta t = 1/N_p$, corresponding to one transition per pair per unit time, in agreement with the transition rates that define the

process. Following each change we update the list of pairs. The trial continues until either no pairs remain (extinction) or a preset maximum time t_m is reached. (In the largest studies reported here, $t_m = 22026 \simeq e^{10}$.) We use a lattice of $L = 5 \times 10^4$ sites, sufficiently large that activity never reaches the boundary of the system for $t \leq t_m$.

Reweighting scheme. We have realized a significant speedup, permitting larger samples and longer durations than in previous studies, by means of a reweighting technique. The basis and details of this method are given in Ref. [36]. Briefly, we run the simulations at a central value, p_0 , of the annihilation probability p , and reweigh the sample to study nearby values $p' = p_0 + n\Delta p$. (We always use p_0 very near p_c , typically $p_0 = 0.07709$ or 0.0771 ; Δp is either 10^{-5} or 5×10^{-6} , depending on t_m .) Suppose that in a particular trial, there have been n_a annihilation events and n_c creation events (successful or not) up to time t . The weight for this sequence of events in a simulation with annihilation probability p' , is

$$\omega(p', p_0; t) = \left(\frac{p'}{p_0}\right)^{n_a} \left(\frac{1-p'}{1-p_0}\right)^{n_c}, \quad (5)$$

which represents the ratio of the probability for this sequence in the process with parameter p' to the corresponding probability for p_0 . In practice, we record the number of pairs, mean-square displacement, and continued survival of a trial at unit time intervals. The simulation estimate for the central value, p_0 , of any property A at time t is, as usual, $\overline{A}_{t;p_0} \equiv N_{tr}^{-1} \sum_{k=1}^{N_{tr}} A_{k,t}$, where $A_{k,t}$ is the value at time t in the k th of a total of N_{tr} independent trials. The corresponding estimate for parameter value p' is $\overline{A}_{t;p'} \equiv N_{tr}^{-1} \sum_{k=1}^{N_{tr}} \omega(p', p_0; t) A_{k,t}$. The reweighting factor ω varies from trial to trial, depending on the number of creation and annihilation events realized up to time t . An analysis of the range of p values for which reweighting is useful is given in Ref. [36].

Application of this method to the CP yielded results of unprecedented precision for critical point and exponents [36]. Beyond the obvious economy of studying various parameter values at once, the fact that the results for all p values come from the same data set eliminates run-to-run fluctuations that tend to obscure the value of p_c . (Our method, of course, does not eliminate fluctuations *per se*. But here the fluctuations affect the results for all parameter

values uniformly. Without reweighting, one has to generate a different sample, with its particular fluctuations, for each parameter value of interest.)

V. RESULTS

A. Critical Point and Spreading Exponents

We determine the survival probability, mean number of pairs, and mean-square distance of pairs from the original seed, expecting that these follow asymptotic power laws at the critical point, and show deviations from power laws for off-critical values of p . To identify $p_c(\phi)$ we follow the widely-used practice of studying the local slopes, $\delta(t)$, $\eta(t)$ and $z(t)$, defined as the derivatives of $\ln P$, $\ln n$, and $\ln R^2$, respectively, with respect to $\ln t$. We evaluate $\delta(t)$ by performing a least-squares linear fit to the $\ln P$ data for a set of 25 equally-spaced values (an increment of 0.1) of $\ln t$; $\eta(t)$ and $z(t)$ are obtained similarly.

In studies of spreading at an absorbing-state phase transition, the local slopes are usually plotted versus t^{-1} . The curves for $\delta(t)$ and $\eta(t)$ typically fall into three groups: those that curve sharply upward are taken as marking supercritical parameter values, those curving sharply downward are associated with the subcritical regime, and those that seem to have a finite limiting value (as $t^{-1} \rightarrow 0$) are consistent with criticality. (The extrapolated value furnishes an estimate for the associated exponent, δ , η , or z . There is often some uncertainty, i.e., two or more parameter values may “look” critical, especially when fluctuations are strong. The curves for $z(t)$ generally provide much less information about the location of the critical point.) The rationale for this practice is that in the one-dimensional CP the leading correction to scaling appears to be $\propto t^{-1}$, that is, for $t \gg 1$,

$$\delta(t) \simeq \delta[1 + at^{-\Delta_1} + bt^{-\Delta_2} + \dots], \quad (6)$$

with $\Delta_1 = 1$. In other cases, however, the dominant correction to scaling may decay more slowly than $1/t$ [47].

In Fig. 1 we plot the local slopes $\delta(t)$ from our spreading studies with $\phi = 0$. (The data are from a set of 2×10^6 trials, extending to $t_m = 22026$. The simulations were performed at $p_0 = 0.07709$, and reweighted to study a series of p values at intervals of $\Delta p = 5 \times 10^{-6}$.) When plotted versus t^{-1} , as in Fig. 1, all of the curves swerve sharply downward; there is no obvious candidate for p_c . At this point we recall an important observation of Ódor et al.: the particle density $\phi(t)$ in the active region approaches its natural value as a power law, $|\phi(t) - \phi_{nat}| \sim t^{-\delta_{DP}}$, with the standard DP exponent $\delta_{DP} \simeq 0.16$ [35]. Given the coupling between the order parameter and the particle density, it is natural to suppose that the slow relaxation of the latter will yield a dominant correction to scaling $\sim t^{-\delta_{DP}}$ rather than $\sim t^{-1}$. We test this hypothesis in Fig. 2, where the $\delta(t)$ data are replotted versus $t^{-\delta_{DP}}$. Evidently, the strong curvature of the $\delta(t)$ plot in Fig. 1 is accounted for by a change in the correction to scaling exponent; the graphs of Fig. 2 are roughly linear. Similar changes attend the switch from t^{-1} to $t^{-\delta_{DP}}$ in the other local-slope plots, for all of the ϕ values studied here.

In Fig. 2, we see that the curve for $p = 0.07707$ is nearly linear, whilst those for 0.077065 and 0.077075 show noticeable curvature. (This visual impression is confirmed by least-squares quadratic fits to the data.) Linear extrapolations of the $\delta(t)$ plots yield $\delta = 0.252$, 0.256, and 0.261 for $p = 0.077065$, 0.07707, and 0.077075, respectively. Based on these results, we estimate $\delta_{\phi=0} = 0.256(4)$. Fig. 3 shows a similar plot for $\eta(t)$, the local slope of the population size. The curves are somewhat less regular, and the most linear plot appears to be that for $p = 0.077075$. Linear extrapolations for $p = 0.07707$, 0.077075, and 0.07708 yield $\eta = 0.218$, 0.211, and 0.204, leading to the estimate $\eta_{\phi=0} = 0.211(7)$. The data for $z(t)$ are plotted in Fig. 4. Here it is difficult to discern p_c ; linear extrapolations over the range $p = 0.077065 - 0.07708$ yield $z_{\phi=0} = 1.245(7)$. Our results are consistent with those reported in Ref. [25] for spreading in an initially empty lattice: $\delta_{\phi=0} = 0.250(5)$, $\eta_{\phi=0} = 0.215(5)$, and $z_{\phi=0} = 1.238(4)$. (The somewhat larger error bars in the present results reflect the uncertainty inherent in extrapolating to $t^{-0.16} = 0$.) Combining the critical point estimates from the analyses of $\delta(t)$ and $\eta(t)$, we obtain $p_c(0) = 0.077073(6)$.

Next we consider spreading in a half-filled environment. Here we performed a total of

1.2×10^6 trials, extending to $t_m = 22026$; in this case we used $p_0 = 0.0771$ as the central simulation value. The local slopes $\delta(t)$ and $\eta(t)$ are shown in Figs. 5 and 6, respectively. Note that $-\delta$ and η approach their limiting values from below, while for $\phi = 0$ the approach is from above. Analyzing the local slopes as above, we find $p_c(1/2) = 0.077087(6)$. The exponent estimates are listed in Table I. Finally, we performed simulations of spreading into an environment with particle density $\phi_{nat} = 0.242$. The central value of p was again 0.07710, and the number of trials 2×10^6 , but the studies extended only to time 8103. Analyses of $\delta(t)$ and $\eta(t)$ (the latter is shown in Fig. 7) yield $p_c(\phi_{nat}) = 0.077093(7)$. The critical exponents for $\phi = \phi_{nat}$, listed in Table I, are in good agreement with the known DP values.

B. Activity and particle density profiles

The discussion of Sec. III motivates our study of the spatial distribution of activity (the pair density) and the particle density in surviving trials. According to the scaling hypothesis [34], at the critical point, the mean order-parameter density $\rho_s(x, t)$ in surviving trials, given an initial seed at $x = 0$ and $t = 0$, should scale as

$$\rho_s(x, t) = t^{z/2-\delta-\eta} R(x^2/t^z), \quad (7)$$

where the scaling function R vanishes for large values of its argument. The hyperscaling relation Eq. (1) implies that the prefactor is $t^{-\delta_{DP}}$. We therefore expect plots of $\rho^*(x^*, t) \equiv t^{\delta_{DP}} \rho(x/t^{z/2}, t)$ to collapse onto a single curve. Figures 8, 9, and 10 show such plots for $\phi = 0$, $1/2$, and $\phi_{nat} = 0.242$, respectively, confirming the anticipated scaling. (The study for $\phi = 0$ was performed using $p = 0.07708$, and those for $\phi = 0.242$ and $1/2$ using $p = 0.07709$; there is no reweighting.) The scaling function has the same qualitative form in all three cases; there is no hint of the plateaulike or bimodal profiles envisaged in Sec. III. The fact that the scaled activity profile is stable for times ≥ 1000 suggests that the local slopes $\delta(t)$, $\eta(t)$ and $z(t)$ have also attained their asymptotic scaling regime, so that the critical exponents can be extrapolated with confidence.

We note also that the rate of spreading is greater, the larger is ϕ . This can be quantified by measuring the mean-square spread; we find $\overline{x^{*2}} \simeq 0.75t$, $1.1t$, and $2.0t$ for $\phi = 0$, 0.242 , and 0.5 , respectively. Most significantly, the definition $x^* \equiv x/t^{z/2}$ involves the ϕ -dependent z values listed in Table I. Were we to use, for example, the standard DP value $z = 1.265$ in x^* for $\phi = 0$ we would find that $\overline{x^{*2}}/t$ approaches zero as $t \rightarrow \infty$.

A similar analysis can be applied to the mean particle density $\phi_s(x, t)$ in surviving trials. Here $\phi_s(x, t)$ is fixed at its initial value ϕ for $x \gg t^{z/2}$, that is, outside the active region, and we expect $\phi_s(x, t) - \phi_{nat}$ to decay $\sim t^{-\delta_{DP}}$ within the active region. These behaviors are reflected in the scaling form

$$\phi_s(x, t) - \phi_{nat} = (\phi - \phi_{nat}) \left[1 - \frac{\rho_s(x, t)}{\rho_s(0, t)} \right] + t^{-\delta_{DP}} F(x^2/t^z). \quad (8)$$

Here the first term on the r.h.s. represents the uniform particle density ϕ outside the active region; the factor in square brackets switches from 1 outside, to zero well inside this region. (For $\phi = \phi_{nat}$, of course, this term vanishes.) The second term represents relaxation of the particle density to its natural value within the active region. To test this scaling hypothesis we plot

$$\phi^*(x^*, t) \equiv t^{\delta_{DP}} \left\{ (\phi_s(x, t) - \phi_{nat}) - (\phi - \phi_{nat}) \left[1 - \frac{\rho_s(x, t)}{\rho_s(0, t)} \right] \right\}, \quad (9)$$

versus x^* . Figures 11, 12, and 13 are scaling plots of $\phi^*(x^*, t)$ for $\phi = 0$, $1/2$, and 0.242 , respectively. The data collapse confirms the observation of Ódor et al. that the particle density exhibits a power-law relaxation to its natural value, $|\phi(t) - \phi_{nat}| \sim t^{-\delta_{DP}}$, within the active region [35].

VI. DISCUSSION

We return to the three clues mentioned in the Introduction. First our simulations, which are the most extensive (in terms of sample size and trial duration), of the PCP to date, shows no evidence for a shift of the critical point with particle density. It is true (see Table

I) that our p_c estimate for $\phi = 1/2$ is slightly higher than that for $\phi = 0$, but the data for the three ϕ values studied show no systematic trend. In particular, our data do not confirm the results reported in Ref. [35], where p_c is given as 0.07704 for $\phi = 0$ and 0.07714 for $\phi = 0.432$ (and would presumably be at least as large, for $\phi = 1/2$), so that $p_c(1/2) - p_c(0) \geq 10^{-4}$. Here, by contrast, we find $p_c(1/2) - p_c(0) = 1.4 \times 10^{-5}$, with an uncertainty of $\pm 1.2 \times 10^{-5}$. To summarize, the present results are incompatible with the relatively large shift reported in Ref. [35], but are quite compatible with there being no shift at all.

In Figures 14, 15 and 16 we plot our results for the spreading exponents δ , η , and z as functions of ϕ , together with results from Refs. [25] and [35]. The overall consistency among these studies leaves little doubt that there is a systematic, roughly linear dependence of the exponents on the particle density.

Our results for the spreading exponents are sufficiently precise to rule out the proposal that z and $\delta + \eta$ are independent of ϕ . While their variation is much smaller than that in δ or η separately, there are significant changes, amounting to a relative variation of about 5% between the extremes $\phi = 0$ and $\phi = 1/2$. The fact that z varies with ϕ was confirmed in our scaling analysis of the activity profile. Finally, as shown in Table I, the generalized hyperscaling relation is satisfied to within numerical uncertainty. Given the variation in z , a compensating variation in $\delta + \eta$ is needed for hyperscaling to hold. That $\delta + \eta$ and z depend on ϕ forces us to abandon what seemed an attractive simplifying hypothesis: the environment affects not only the likelihood of survival, but (to a lesser extent) the scaling properties of trials that do survive.

Can we understand nonuniversal spreading in models with INAC? Thus far, attempts to identify a marginal parameter in a renormalization group analysis of the PCP and allied models have not borne fruit. Nonuniversality does appear to be associated with a long memory, due to the slow relaxation of an auxiliary field coupled to the order parameter. Such a memory term appears in a field theory that successfully predicts the static critical behavior of the PCP [27], and that reproduces (numerically) nonuniversal spreading [32]. Moreover, varying exponents have been observed in one-dimensional models with a unique absorbing

configuration and a slowly-relaxing memory of the initial condition [29,30]. Explaining the nonuniversality of the spreading exponents, and predicting their values as a function of the particle density, remain as theoretical challenges.
